Introduction to kd-trees

- Dimension of data is k (but common to say k-d tree of dimension 3 instead of 3d-tree).
- kd-trees are binary trees
- Designed to handle spatial data in a simple way
- For n points, $O(n)$ space, $O(\log n)$ height (if balanced), supports range and nearest-neighbor queries.
- Node consists of
 - Two child pointers,
 - Satellite information (such as name).
 - A key: Either a single float representing a coordinate value, or a pair of floats (representing a dimension of a rectangle)

Basic Idea Behind kd-trees

Construct a binary tree

- At each step, choose one of the coordinate as a basis of dividing the rest of the points
- For example, at the root, choose x as the basis
 - Like binary search trees, all items to the left of root will have the x -coordinate less than that of the root
 - All items to the right of the root will have the x -coordinate greater than (or equal to) that of the root
- Choose y as the basis for discrimination for the root's children
- And choose x again for the root's grandchildren

Note: Equality (corresponding to right child) is significant

Example: Construct kd-tree Given Points

- Coordinates of points are (35, 90), (70, 80), (10, 75), (80, 40), (50, 90), (70, 30), (90, 60), (50, 25), (25, 10), (20, 50), and (60, 10)

- Points may be given one at a time, or all at once.
- Data best visualized as shown below

Building: Dynamic Insertion

```
KDNode insert ( point p, KDNode t, int cd) {  
    if (t == null) t = new KDNode (p);  
    // sets up node.data.x and node.data.y  
    else if (p == t.data) ... // duplicate  
    else if (p.cd < t.data.cd)  
        t.left = insert (p, t.left, cd+1);  
    else t.right = insert (p, t.right, cd+1);  
    return t;  
}
```

- Initial call: `root = insert (p, root, 0);`
- Each node is associated with a rectangular region
- Tree is “balanced” if points are given in random order
- Or if all points are given in advance

Page 6 of 100

[Go Back](#)[Full Screen](#)[Close](#)

Building: The Static Case

- Assume points are sorted on *both* x and y in a composite array S
- $S[x]$ corresponds to a list of points sorted by x .

```
KDNode buildTree(SortedArray S, int cd) {  
    if (S.empty()) return null  
    else if S.singleton() return new KDNode(S[x][0], cd);  
    else {  
        m = median (S, cd) // median (cutting dimension)  
        left = leftPoints(S, cd); right = S - left;  
        t = new KDNode(m);  
        t.left = buildTree(left, cd+1);  
        t.right = buildTree(right, cd+1);  
        return t  
    }  
}
```

- $T(n) = kn + 2T(n/2)$, so the algorithm takes $O(n \log n)$ time.

Remove Requires Finding Minimum

- Given a node, and a cutting dimension, find the node with minimum value (with respect to that cutting dimension)

```
Point findmin (KDNode t, int whichAxis, int cd) {  
    if (t == null) return null;  
    else if (whichAxis == cd)  
        if (t.left == null) return t.data;  
        else return findmin(t.left, whichAxis, cd+1);  
    else return  
        minimum(t.data, findmin(t.left, whichAxis, cd+1),  
                findmin(t.right, whichAxis, cd+1), i);  
}
```

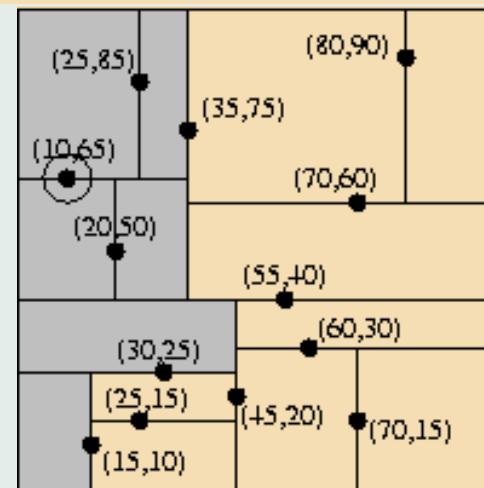

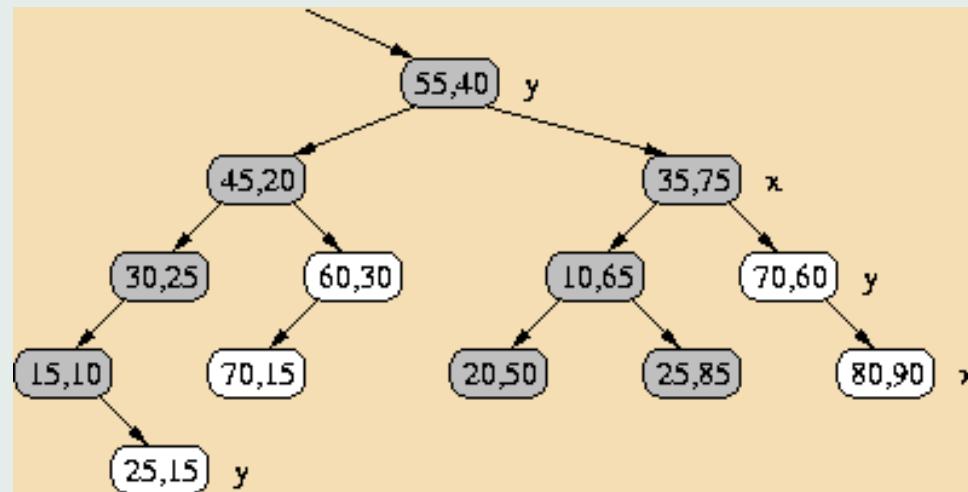

- If tree is balanced, **findmin (root)** takes no more than $O(\sqrt{n})$ time in the worst case.

Basic Idea Behind Removing

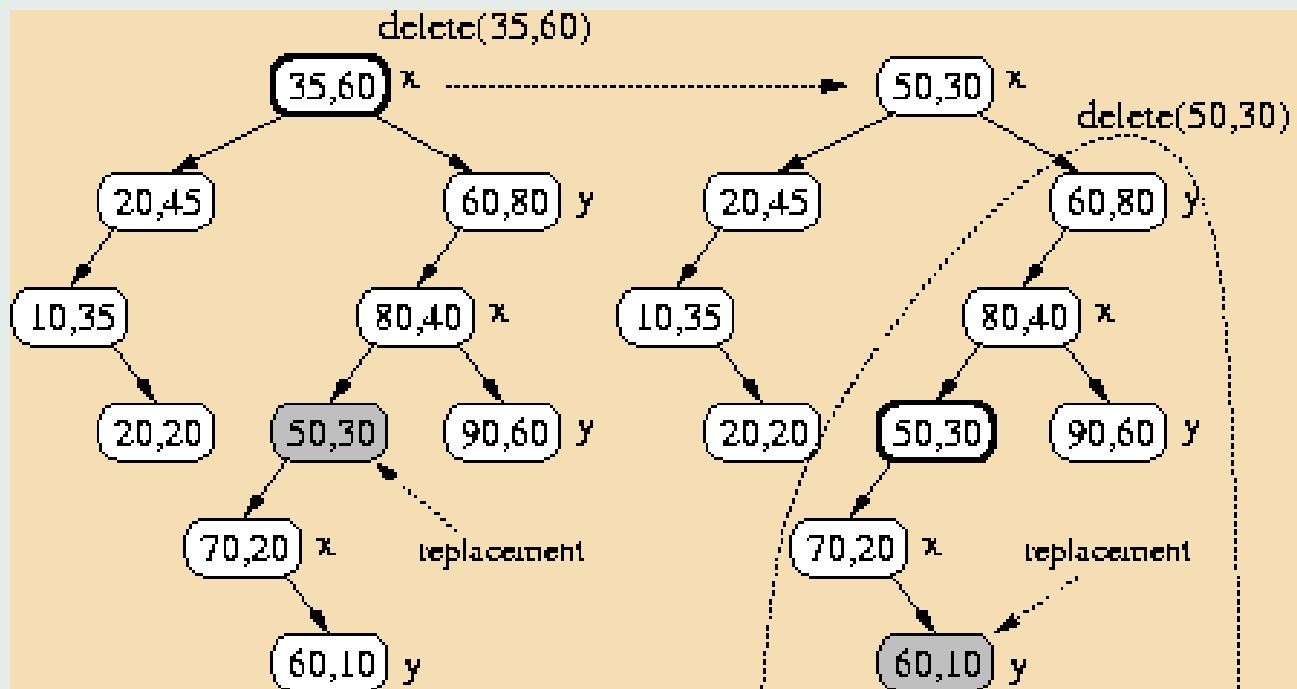

- Want to remove point $p = (a, b)$
- First find node t which has this point
- Node t discriminates on x (say)
 - If t is a leaf node, replace it by null
 - Otherwise, find a replacement node r with coordinates (c, d)
 - Replace the data at t by (c, d) . The kd-tree structure must not be violated
 - Recursively remove point $p = (c, d)$
- Finding the replacement
 - If t has a right child, use the inorder successor
 - Otherwise minimum value of the left child is appropriately used

Remove Takes $O(\log n)$ Time

```
KDNode remove (KDNode t, Point p, int cd) {  
    if(t == null) return null;  
    else if(p.cd < t.data) t.left = remove(t.left, p, cd+1);  
    else if(p.cd > t.data) t.right = remove(t.right, p, cd+1);  
    else {  
        if(t.right == null && t.left == null) return null;  
        if(t.right != null)  
            t.data = findmin(t.right, cd, cd+1);  
        else {  
            t.data = findmin(t.left, cd, cd+1);  
            t.left = null;  
        }  
        t.right = remove(t.right, t.data, cd+1);  
    }  
    return t;  
}
```

We expect to delete nodes at leaf level. If tree is balanced, we expect `remove()` to take $O(\log n)$ time
